Facts, Role Models, and Frontline Effort: Evidence from Garment Workers in Vietnam*

Yuyu Chen Lukas Hensel Xinjue Yao

November 2, 2026

Abstract

Complex and opaque pay systems can weaken the link between incentives and worker behavior. We conduct a field experiment with 1,749 sewing-machine operators in Vietnam, using cross-randomized social-media videos about pay incentives. The information increases worker effort, potentially because of increased occupational self-efficacy. However, information also shifts workers toward less difficult tasks, offsetting the effort effect and leaving total output and earnings unchanged. Adding a story of a successful worker backfired and offset the effort gain. This shows that information about incentive systems must account for the multidimensionality of behavior and perceived agency at work.

Keywords: Information provision, Role model, Worker effort, Self-efficacy, Field experiments

1 Introduction

Workers often face complex incentive systems that make it difficult to act optimally. Current pay may be a non-linear function of effort and output. When workers are boundedly rational, this complexity can alter behavior even if the underlying incentives remain unchanged (Abeler et al., 2025). Workers must therefore assess their own performance and infer how effort maps into rewards. Yet learning may be incomplete and workers' misperceptions can persist over time (Hoffman and Burks, 2020; Huffman et al., 2022).

Moreover, the path to success is often more complex than any single pay rule. Career progression may require sustained effort, skill acquisition, and recognition by others. Stories of successful workers can make this path concrete and memorable, potentially strengthening workers' response to factual information (Bernard et al., 2026; Graeber et al., 2024). But narratives may also shape how workers interpret those facts. A relatable example may raise the perceived return to effort, whereas an exceptional one may make information about average returns seem less relevant (Lockwood and Kunda, 1997; Nguyen, 2008). Whether facts and a role-model story reinforce or offset each other is therefore an empirical question.

This paper asks whether information about workplace incentives and a role-model story affect worker behavior, separately and jointly. We answer this question in a four-arm field experiment involving 1,749 mostly female sewing-machine operators at two garment factories in northern Vietnam. We randomly vary exposure to factual information and to a role-model story. Workers in the information-only arm watched videos presenting factual and actionable information about wages and the returns to effort and skill. Workers in the role-model-only arm watched videos about a female worker's early difficulties, professional recognition, and improved financial circumstances. A third group watched both sets of videos, while a fourth watched placebo videos on non-work topics featuring the same worker. This factorial design identifies the effect of each component and whether the story strengthens or weakens the response to the information package.

We measure behavior with administrative records. Our primary effort index combines absenteeism, hours worked, and receipt of the full attendance bonus during the two months after the intervention. We also examine task assignments, production value, and wages, allowing us to distinguish greater workplace presence from greater productivity while at work. We report four main findings.

First, the information treatment increases work effort. Relative to the placebo treatment, it raises the effort index by 0.19 control-group standard deviations ($p = 0.002$). This increase reflects a 1.8-percentage-point reduction in absenteeism from a placebo mean of 6.4 percent ($p = 0.017$), as well as a 0.12-standard-deviation increase in daily hours

worked.

Second, the combined treatment does not preserve the gain produced by information alone. Relative to information alone, the combined treatment lowers the effort index by 0.2 standard deviations ($p = 0.001$), leaving a combined-treatment effect of -0.008 standard deviations ($p = 0.903$). The role-model treatment alone also has no detectable average effect on effort. Suggestive heterogeneity indicates that this attenuation is concentrated among workers who are less similar to the featured worker. Among workers below the median of the similarity index, adding the story reduces effort by 0.32 standard deviations relative to information alone ($p = 0.076$); the corresponding estimate among above-median workers is -0.04 standard deviations and statistically insignificant.

Third, we provide evidence that changes in occupational self-efficacy drive the effort response to the information treatment. Among workers with below-median baseline occupational self-efficacy, information raises effort by 0.35 standard deviations ($p = 0.002$). The effect is 0.29 standard deviations smaller among workers with above-median self-efficacy ($p = 0.052$).

Finally, information reduces the variety and difficulty of the production skills workers use, despite emphasizing the returns to versatility and difficult tasks. One interpretation is that workers focus on immediately adjustable effort margins rather than negotiate for more advanced and better-paid tasks.

The earnings results are consistent with offsetting changes in effort and skill use. Information reduces hourly production value by 6.3 percent ($p = 0.073$), but workers spend more hours at work and receive higher attendance bonuses. The estimated effect on average monthly earnings is close to zero with a tight confidence interval.

We contribute to a literature showing that information about pay, relative performance, career ladders, and promotion incentives can change employee behavior (Awaysheh et al., 2023; Card et al., 2012; Cullen and Perez-Truglia, 2022; Deserranno et al., 2025; Gosnell et al., 2020; Wu et al., 2022). Related evidence shows that workplace communication tools can interact rather than operate additively (Delavallade, 2021). We show that factual and actionable information about a firm's incentive system can increase short-run effort when embedded in a series of social-media videos. We identify a general increase in self-efficacy rather than a simple shift in domain-specific beliefs as a likely driver of the effect. Existing work focuses on one-off information interventions delivered in the context of the research project. This distinction matters because responses to information can depend on how it is presented and the context in which it is received (Haaland et al., 2023).

Our findings also qualify recent evidence that narratives can strengthen information by facilitating mental simulation and memory retrieval (Graeber et al., 2026). In our setting, a success narrative makes information less effective. The stronger attenuation

among workers who are less similar to the featured worker is consistent with the possibility that perceived relevance shapes narrative effects, although the experiment does not identify this mechanism directly.

More broadly, we contribute to experimental research on role models, aspirations, and learning from successful peers (Ahmed et al., 2024; Bernard et al., 2026; Breda et al., 2023; Brooks et al., 2018; Cecchi et al., 2022; Dalton et al., 2021; Lafortune et al., 2018; Porter and Serra, 2020; Riley, 2024). Most causal evidence comes from education, entrepreneurship, or household investment and generally finds positive effects of role-model exposure. Two exceptions are Narciso et al. (2026), who find no effect on entrepreneurial behavior, and a school-based experiment by Nguyen (2008), which reports that adding a role model attenuates an information treatment. Within established firms, the closest evidence examines richer peer interactions, including structured advice, knowledge sharing, and mentorship (Chen et al., 2025; Sandvik et al., 2020, 2026).

We instead study a scalable success narrative delivered to incumbent production workers through a familiar social-media channel while holding the messenger constant. The role-model treatment alone has no detectable average effect, and the combined treatment does not preserve the effort response produced by information alone. These findings show that a narrative that is ineffective on its own can still weaken the response to an otherwise effective information package.

2 Conceptual Framework

To understand how information about the returns to effort and exposure to role models may interact in shaping effort choices, we present a simple framework. Workers choose effort $e_i \geq 0$ to equate the marginal expected return to effort with its marginal cost:

$$\left.\frac{dE[w_i(e_i)]}{de_i}\right|_{e_i=e_i^*} = \frac{dc_i(e_i^*)}{de_i}, \tag{1}$$

where $E[w_i(e_i)]$ is worker i's expected earnings and other benefits from providing effort, and $c_i(e_i)$ is the cost of providing effort, assumed weakly increasing and convex. We treat $c_i(\cdot)$ as fixed throughout: neither treatment is designed to, or assumed to, change how costly workers perceive effort to be. All treatment effects therefore operate through the perceived marginal return $\frac{dE[w_i(e)]}{de}$.

The information intervention is designed to shift this perceived return upward, i.e., $\left.\frac{dE[w_i(e)]}{de}\right|_{\text{info}} > \left.\frac{dE[w_i(e)]}{de}\right|_{\text{control}}$. Holding the cost of effort fixed, standard monotone comparative statics on (1) immediately imply $e_i^*(\text{info}) > e_i^*(\text{control})$. This is closely related to workers' self-efficacy—their belief in their own capacity to convert effort into successful outcomes—a link we develop further later in the paper.

The role model intervention narrated how a character overcame difficulties before becoming successful. Rather than treating this as an independent signal about the returns to effort, we think of it as conditioning how workers interpret and internalize the information intervention. If the role model is relatable—workers see the character's trajectory as attainable given their own circumstances—exposure to the role model should amplify the belief revision induced by the information treatment: the statistical evidence of high returns becomes more credible and personally relevant once workers see a concrete, similar individual who achieved them. If, instead, the role model is perceived as too exceptional or dissimilar, exposure should dampen, or even reverse, the same belief revision: workers may discount the returns shown in the information treatment as applying only to people unlike themselves. Since the cost of effort is unaffected in either case, the sign of the combined-treatment effect on effort follows directly, via (1), from the sign of this amplification or attenuation: a relatable role model reinforces the information treatment, while an unrelatable one can undo it, or worse, turn its effect on effort negative.

Taken purely as a moderator, this channel implies that the role model treatment on its own—without the information treatment—has no belief revision left to amplify or dampen, and should therefore leave effort unchanged, $e_i^*(\text{RM alone}) = e_i^*(\text{control})$. A role model may, however, also act directly on the perceived return to effort by shifting workers' reference point, or target, for what counts as an attainable outcome, independent of any accompanying statistical information: observing a similar, successful individual can itself raise $\frac{dE[w_i(e)]}{de}$ by recalibrating the benchmark against which a worker judges her own prospects. Whether this reference-point channel raises or lowers effort again turns on relatability: a role model adopted as a relevant benchmark should raise the perceived return and hence effort on its own, while one who is not may lower it instead.

Both the moderation of the information treatment and the direct reference-point channel are governed by the same underlying condition: whether the role model falls within the worker's "aspirations window" (Genicot and Ray, 2017; Ray, 2006)—the limited set of comparable others by reference to which individuals form beliefs about what is attainable for themselves. Role models within this window raise perceived returns to effort, whether by reinforcing the information treatment or by shifting the reference point directly; role models outside it are not incorporated as evidence about one's own prospects and may instead lower perceived returns (Dalton et al., 2016).

3 Context and Data

We conduct the experiment in two ready-made-garment factories located in Hai Ha County, Quang Ninh Province, Northern Vietnam. These factories are subsidiaries of a large apparel export company in East China, which began investing in Vietnam in 2016. The first

factory was completed and started production in 2017, followed by the second factory in early 2022. By the end of 2023, the two factories employed more than 2386 sewing workers. Both factories mainly produce clothes for export, supplying products to major retailers in 26 countries.

The firm coordinates the production schedule at the production line level. Each production line produces one product at a time, with production targets set by the industrial engineering team. Within each line, work is organized around interdependent tasks performed by individual workers. Line managers assign tasks to individual workers in order to balance the workload across the line and maximize final garment output. Typically, this happens based on workers' skills, preferences, and availability. When new tasks are available, workers can express interest in working on new, unfamiliar sewing tasks to increase their portfolio of skills. Training on new skills is typically administered by line managers on the job. Workers are regularly offered overtime at higher wages, but are free to turn down this offer.

Data We make use of administrative records generated through the production process. We draw data from four main sources: (1) daily production data, which capture workers' productivity and skill utilization; (2) monthly wage records, which include piece-rate pay, bonuses, and subsidies; (3) daily attendance logs, used to assess absenteeism and working hours; and (4) human resources data, which provide comprehensive background and demographic information for all employees. Additionally, we conducted a baseline survey and take-up surveys with a subsample of workers. Right after the intervention, we conducted an additional endline survey targeting the full sample. The surveys are described in detail in Section 4.2.

Sample We approached all frontline sewing workers at the two factories in person and asked them to participate in the study. Line managers and other technical and managerial staff were not included in the experimental sample. The only condition for eligibility was that they had an active Facebook account or created a Facebook account with the support of the field officers. During the recruitment drive, field officers asked workers to join an experimentally determined Facebook group that serves to administer the intervention. In total, 73.3% of the 2,386 frontline workers we approached agreed to take part in the experiment. The main reason workers did not enroll was that they did not use social media.[1]

[1]Tables A.1 and A.2 report participation and baseline balance by assignment arm. Table A.3 compares joiners with nonjoiners. Relative to nonjoiners, joiners were 1.4 years younger and had stronger baseline employment outcomes: they earned about 102 dollars more per month, performed advanced tasks more frequently, had a 0.7-percentage-point lower absenteeism rate, and worked 0.11 more hours per attended day.

Table 1 presents summary statistics for the workers included in our experiment. All variables are calculated using administrative data from the baseline period (August to October 2023). 79% of the sampled workers are female. The median age is 28, with workers' ages ranging from 18 to 54 years. The median level of education, nine years, corresponds to a middle school degree. The median tenure at the firm is 22 months. Thus, the sample consists mostly of experienced workers who have settled into factory life and who have developed the basic skills required to operate sewing machines.

Table 1: Summary Statistics

	Mean (1)	Median (2)	P10 (3)	P90 (4)	SD (5)	Obs. (6)
Panel A: Demographics						
Female	0.79	1.00	0.00	1.00	0.41	1749
Tenure (months)	30.01	22.18	2.89	72.31	24.62	1749
Age	29.17	28.00	20.00	40.00	7.88	1749
Years of schooling	9.92	9.00	6.00	12.00	2.38	1719
Panel B: Productivity and skills						
Average daily piece-rate value[a,b]	4.08	3.48	1.72	7.31	2.48	1710
Average monthly piece-rate value[a]	103.03	88.14	41.60	186.72	64.41	1710
Average monthly piece-rate earnings[a]	766.14	792.93	598.03	907.52	165.28	1747
Average monthly gross earnings[a]	1152.34	1185.22	937.69	1318.43	198.29	1747
Worked on any difficult task[c]	0.66	1.00	0.00	1.00	0.47	1710
Fraction of workdays doing difficult tasks[c]	0.46	0.38	0.00	1.00	0.44	1710
Average difficult-task output[a,c]	2.36	0.76	0.00	6.80	3.17	1710
Average difficulty of daily tasks[c]	2.36	2.18	1.30	3.44	0.74	1710
Average number of tasks per day	2.36	2.00	1.08	3.92	1.60	1710
Panel C: Effort measures						
Absenteeism rate	0.04	0.03	0.00	0.10	0.07	1710
Average full-attendance bonus	55.72	63.20	40.14	63.25	13.09	1747
Fraction of attendance bonus received[d]	0.95	1.00	0.81	1.00	0.13	1735
Received all the full-attendance bonus	0.49	0.00	0.00	1.00	0.50	1747
Average daily working hours[e]	9.97	10.00	9.88	10.00	0.18	1747

Notes: **Table 1 reports baseline summary statistics for the 1,749 frontline sewing workers enrolled in the experiment.** All variables are measured over the baseline period, August–October 2023.
[a] All monetary variables are expressed in 2023 USD. We convert Vietnamese dong using the World Bank PPP conversion factor for household and nonprofit institutions serving households (NPISHs) final consumption expenditure (1 USD = 7,114.3 VND).
[b] Daily piece-rate value is averaged over all the scheduled working days.
[c] Difficult tasks comprise A- and B-level tasks. To calculate average task difficulty, we assign values of 4, 3, 2, and 1 to A-, B-, C-, and D-level tasks, respectively.
[d] The fraction of the attendance bonus received is conditional on receiving a positive bonus. For each worker, we calculate the fraction of the full bonus received in each month with a positive payment and then average this fraction across those months.
[e] Average daily working hours are calculated conditional on attendance.

Compensation Gross monthly earnings comprise piece-rate pay, overtime pay, bonuses, subsidies, and small payroll adjustments. Piece-rate and overtime pay constitute the two

largest components.

The piece-rate component depends on the total value of the tasks a worker completes during the month, which the firm records electronically, and the firm's monthly revenue. The value of a task depends on its target completion time and difficulty.[2] The firm uses production value as a measure of individual productivity. Each month, the firm establishes a wage pool equal to a fixed share of revenue and allocates it across workers in proportion to their accumulated production values. After applying the monthly conversion rate, the firm makes payroll adjustments—including topping up workers whose calculated pay falls below the applicable local minimum wage—which compress the dispersion of piece-rate pay relative to production value. Overtime compensation is calculated separately from piece-rate pay. It is paid at 150 percent of the hourly wage set by the firm at 3.16 USD PPP. Workers are not explicitly informed of the formula or the value assigned to each task; they observe only the aggregate payment reported on their monthly pay slips.

On average, workers generate a production value of 103 USD per month. There is substantial heterogeneity: the 10th and 90th percentiles are 41.6 and 186.7 USD, respectively, and the interquartile range is 68.1 USD. The corresponding piece-rate payment averages 766 USD per month, equivalent to 66.5% of average gross monthly earnings. Overtime pay averages an additional 228 USD, or 19.7% of gross earnings.

Workers may also receive attendance and other bonuses. The full-attendance bonus is 63.25 USD for workers who attend every scheduled workday during the month. The average attendance-bonus payment is 55.72 USD, or 4.8% of gross monthly earnings. The remaining approximately 8% consists of paid-leave and holiday pay, other bonuses and subsidies, and small payroll adjustments. Median gross monthly earnings are 1,185 USD.

Worker effort With respect to effort, we focus on three prespecified effort measures: absenteeism rate, daily working hours, and monthly attendance bonus. The average absenteeism rate is 4%, meaning that, on average, workers are absent for about one day per month (given a typical 26-day work month). Conditional on attendance, the average daily working hours are 9.97, with a range from 7.87 to 11 hours per day. This variation is caused by a mix of overtime choices and late arrivals or early departures. Absence, lateness, or early departure can disrupt the coordinated production schedule and can cause a worker to lose the attendance bonus. Notably, only 49% of workers received the full attendance bonus in each of the three months before the intervention. These statistics suggest that there is substantial scope for workers to increase their effort.

[2]The firm classifies sewing tasks into four skill levels—A, B, C, and D—in descending order of difficulty. During the three-month baseline period, 66% of workers performed at least one A- or B-level task, which the firm classifies as difficult. On average, workers performed difficult tasks on 46% of their workdays.

4 Interventions and Experimental Design

We evaluate two interventions designed to increase workers' effort, promote their skill acquisition, and ultimately enhance their productivity. The interventions are structured to resemble the short-form social media content commonly consumed by workers during their leisure time. Each intervention comprises seven short videos, which are delivered electronically at a pace of one video every two to three days through private Facebook groups established at the outset of the study. To encourage engagement, we administer weekly follow-up surveys with incentives for participants who correctly answer questions about the video content.

Workers are randomly assigned to one of four groups:

Information intervention: Workers in this group receive videos presenting information about average wages for various worker subgroups, including by attendance levels and difficulty of tasks. The videos also offer practical advice on how to improve effort and acquire new skills. The purpose of these videos is to highlight the returns to effort and skill investment and to provide guidance on how to translate intentions into practice.

Role model intervention: Workers in this group view videos featuring the life of a successful production worker in the factory. The videos narrate how she overcame obstacles to become a successful worker and how her private life has also improved over time. These videos are intended to inspire workers by demonstrating that workplace success is feasible and beneficial.

Combined intervention: Workers in this group receive the full set of videos from both the information and role model interventions.

Placebo group: Workers in this group are shown placebo videos depicting the daily life of a production worker, but without any work-related content. This serves as a control for the effect of simply watching short-form videos about production workers, regardless of their relevance to work.

To hold the number of videos constant across arms, every group received 15 videos in total. Before the treatment period, all groups received one common introductory video. During the treatment period, the information-only group received seven information videos and seven placebo videos; the role-model-only group received seven role-model videos and seven placebo videos; the combined group received seven information videos and seven role-model videos; and the placebo group received 14 placebo videos. All videos feature the same worker from the factory. The actor is a successful employee of the firm, and the role-model videos are loosely based on her experience. She is 30 years old, has one child, and has worked at the firm for nearly three years. Her average gross

monthly earnings rank in the top 2 percent of employees in the same factory's sewing workshops.

The videos were produced in Vietnamese. When publishing them, we did not enable the platform options "Allow download" or "Allow sharing," thereby preventing the sharing of videos outside the private groups. The content of each video intervention is summarized in Table A.5.

4.1 Randomization

Randomization was conducted in two stages, as illustrated in Figure 1A. In the first stage, we randomly assigned 59 production lines to either high-intensity or low-intensity groups. Two-thirds of the production lines were designated as high-intensity lines, while the remaining one-third were assigned to the low-intensity group. On high-intensity lines, 90% of workers were allocated to one of the three treatment groups, whereas on low-intensity lines, only 50% of workers received any of the treatments. This allocation strategy ensured that, overall, approximately 25% of workers were assigned to the placebo group. The randomized saturation stage allows us to test for spillovers within production lines.[3]

In the second stage, workers within each production line were randomly assigned to specific intervention groups. Within each production line, workers assigned to an active treatment were divided equally among the information-only, role-model-only, and combined arms. Across the full sample, the four experimental arms were approximately equal in size.

4.2 Timeline

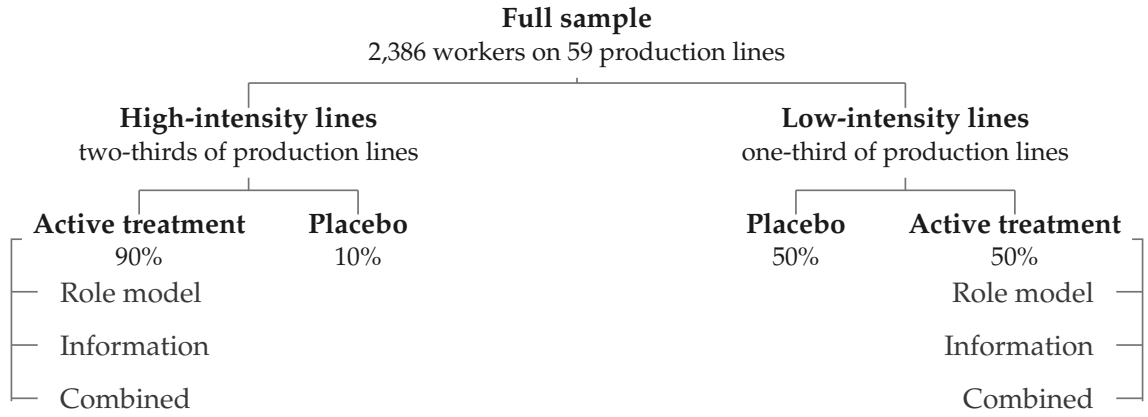

Figure 1B summarizes the sequence of recruitment, treatment delivery, and outcome measurement. We assigned workers to experimental groups before registration, which took place in late November of 2023. A common introductory video and the baseline survey followed in the first week of December, before any treatment content was released.

The treatment period ran from December 10–27. Each group received 14 treatment or placebo videos, and we administered two brief weekly surveys to measure video exposure and content recall. The endline survey, conducted from December 30, 2023, through January 14, 2024, measured post-treatment self-efficacy and demand for skill training. Table A.6 reports the complete video-posting and survey schedule.

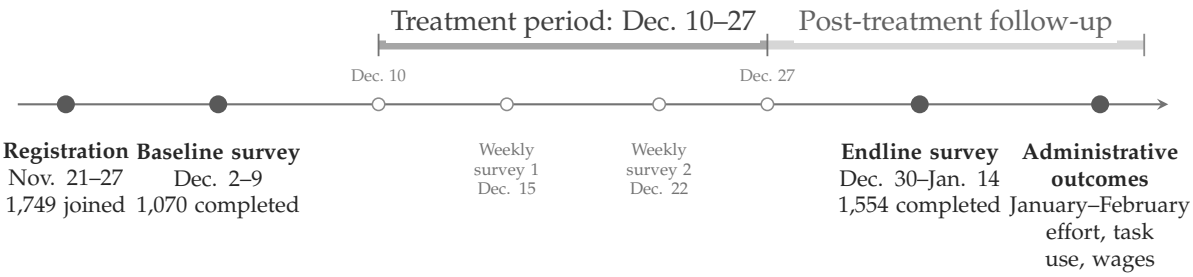

Our primary administrative outcomes cover January and February 2024 and include attendance, working hours, task assignments, production value, and earnings. The pre-analysis plan specified a three-month follow-up, but March coincided with an unusually

[3]We find limited evidence of such spillovers. We therefore focus on direct assignment effects and report the spillover specification and full results in Appendix C.6.

Figure 1: Experimental Design and Timeline

(A) Two-stage randomization

(B) Implementation and measurement timeline

Notes: **Figure 1 displays the experimental design and timeline.** Panel A illustrates the two-stage randomization. First, 59 production lines were assigned to high or low treatment intensity. Two-thirds were high-intensity lines, on which 90% of workers were assigned to an active treatment; the remaining lines were low-intensity lines, on which 50% received an active treatment. Second, active-treatment assignments within each line were divided equally among the information-only, role-model-only, and combined arms. Panel B shows registration, intervention delivery, survey measurement, and the administrative follow-up period. Assignment occurred before registration, and workers had not seen group-specific content when deciding whether to join their assigned Facebook group. One common introductory video preceded the 14 treatment or placebo videos shown during the treatment period.

large intake of new workers and mandatory training that changed the production environment. Tables D.1 and D.2 report the prespecified three-month estimates for the main outcomes. Table C.1 presents monthly treatment effects through March.

4.3 Specification

We estimate the effects of the information, role model, and combined interventions using the following specification:[4]

$$y_i = \beta_0 + \beta_{info} treat_{info,i} + \beta_{rm} treat_{rm,i} + \beta_{comb} treat_{comb,i} + \Gamma X_i + \gamma_l + \epsilon_i \quad (2)$$

Here, $treat_{info,i}$ ($treat_{rm,i}$) is an indicator variable for whether worker i received only the information (only the role model) treatment, while $treat_{comb,i}$ indicates receipt of both treatments. The coefficients β_{info}, β_{rm}, and β_{comb} respectively capture the causal effects of the information-only, role model-only, and combined treatments, each relative to the placebo group.

The vector X_i contains control variables selected for each outcome using post-double-selection (PDS) LASSO, including demographic characteristics and baseline values of the outcome variables (where available).[5] γ_l denotes line fixed effects to account for the stratified randomization at the production line level. Standard errors are heteroskedasticity-robust.[6]

5 Main Results

This section describes take-up and effects of the intervention on worker effort.

5.1 Take-up Rates Over Time

Facebook take-up was high and similar across the active-treatment arms (Figure A.1). About 70 percent of workers viewed each video on the day it was posted, rising to 78–85 percent within a week; videos also drew 55–60 reactions. Weekly surveys likewise indicate high exposure: 97.6 percent of responses reported watching at least one recent video, and 87.6 percent correctly answered a content question. Table A.7 reports the detailed measures.

[4] We pre-registered the analysis of this experiment at https://www.socialscienceregistry.org/trials/12457. Equation 2 differs slightly from the prespecified specification, which includes the treatment-component indicators and their interaction. However, the prespecified interaction term can be recovered as $\beta_{comb} - \beta_{info} - \beta_{rm}$. We report this test of additivity of treatment arms in our main tables.

[5] Our results are robust to re-estimating the main outcomes using production-line fixed effects without additional baseline controls. Table D.3 shows that results remain very similar in magnitude and precision.

[6] Table D.4 reports randomization-inference p-values that reproduce the experiment's two-stage assignment procedure.

5.2 Effects on Worker Effort

Table 2 reports the treatment effects on worker effort. Column 1 presents the prespecified effort index, which combines absenteeism, working hours conditional on attendance, and the attendance bonus (columns 2–4), averaged over the first two post-treatment months. Higher values indicate greater worker effort. Appendix B.1 details the index construction, standardization, and treatment of missing data.

Table 2: Treatment Effects on Worker Effort

	Effort outcomes			
	(1) Effort index	(2) Absenteeism	(3) Working hours	(4) Attendance bonus

Notes: **Table 2 shows that only the information-only treatment group increased work effort.** Outcomes are measured using administrative records from the post-treatment period from January to February 2024. Column 1 reports the *Effort Index*, an inverse-covariance-weighted index of the three effort outcomes in columns 2–4. The index is standardized using the control-group distribution, so that the control group has a mean of zero and a standard deviation of one. Higher values indicate greater worker effort. The index uses available components and is described fully in Appendix B.1. *Absenteeism* is the fraction of scheduled workdays on which the worker was absent. Approved leave and maternity leave are counted as absences; days after employment exit are excluded. *Working Hours* is average daily working hours conditional on attendance. *Attendance Bonus* is the worker's average monthly full-attendance bonus, in 2023 USD PPP. Regressions include production line fixed effects. Additional control variables are selected separately for each outcome using post-double-selection LASSO from a set of pre-treatment covariates, including baseline demographic characteristics, productivity measures, effort measures, and skill-use measures. Heteroskedasticity-robust standard errors are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The information-only treatment increases the effort index by 0.193 standard deviations relative to placebo ($p = 0.002$). All three components move toward greater effort. Monthly absenteeism falls by 1.8 percentage points ($p = 0.017$), or 28 percent of the 6.4 percent placebo mean and 0.16 placebo standard deviations. This equals 0.47 fewer absence days per month—nearly one additional workday over two months. Conditional daily hours rise by 0.03 hours (0.78 hours per month; $p = 0.039$), or 0.12 placebo standard deviations. The attendance bonus rises by 1.447 USD, or 0.09 placebo standard deviations, although the estimate is imprecise ($p = 0.158$). The absenteeism response is the largest component in both economic and statistical terms. These results are consistent with information raising the perceived value of effort: the videos described earnings, returns to effort, and feasible ways to improve workplace performance.

By contrast, the role-model-only treatment changes the effort index by only -0.031 standard deviations ($p = 0.690$). The component estimates are also statistically insignificant, providing no evidence that the role-model videos increased workers' perceived returns to effort. This is not because role-model videos are watched less. Indeed they have 13.8 percent more views than information videos (Table A.8).

Adding the role model to the information treatment reduces the effort effect by 0.20 standard deviations relative to information alone ($p = 0.001$). The combined-treatment effect is therefore close to zero (-0.01 standard deviations; $p = 0.903$), with corresponding attenuation across all three index components. We therefore reject the prespecified hypothesis that the two treatments are complements: the combined effect is 0.171 standard deviations below the sum of the component effects ($p = 0.080$).

We find limited evidence of attention crowd-out. Relative to the corresponding standalone arms, the combined intervention reduces views of information videos by 7.8 percent ($p = 0.430$; column 2 of Table A.8) and increases views of role-model videos by 8.7 percent ($p = 0.016$). Both estimates shrink after controlling for posting order (columns 5–8), suggesting that content timing explains part of the engagement difference. Nevertheless, the modest magnitudes—and the engagement gap already present in the standalone arms—make differential attention unlikely to be the main explanation for the attenuation of the information treatment effect.

The role of similarity. The backfiring effect of the role model treatment may arise because the featured worker appeared out of reach or insufficiently relatable. We examine this possibility using an index that measures each worker's similarity to the role model along four characteristics visible in the videos: age, parenthood, tenure, and gender. For age and tenure, similarity decreases with distance from the featured worker; for parenthood and gender, it indicates whether the characteristics match. The index averages these four components, with higher values indicating greater similarity.

Table C.2 shows that the combined-treatment effect is 0.32 standard deviations larger among workers with above-median similarity to the role model than among those with below-median similarity ($p = 0.076$). Among high-similarity workers, the effect is 0.147 standard deviations ($p = 0.231$), close in magnitude to the information-only effect. The corresponding difference for the role-model-only treatment is also sizable but imprecisely estimated (0.187 standard deviations; $p = 0.455$).

These patterns suggest that similarity mitigates the negative effect of adding the role model. Yet they provide no conclusive evidence of a positive role-model effect, either alone or with information. Effective role-model interventions may therefore also require calibrating the attainability of the featured worker's success to the target population.

5.3 Mechanism: Worker Self-efficacy

The information intervention was designed both to communicate the returns to effort and to help workers overcome barriers to exerting it. Put differently, we aimed to raise occupational self-efficacy—the belief in one's ability to succeed at work (Bandura, 1977). We examine this channel in two ways: heterogeneity by baseline self-efficacy and treatment effects on endline self-efficacy.

The baseline and endline surveys measure occupational self-efficacy using the six five-point Likert items from Rigotti et al. (2008). We standardize the items and combine them in a variance-covariance-weighted index. Appendix B.4 provides measurement details, and Figure B.1 plots the baseline distribution.

Table 3 compares treatment effects above and below the median of baseline self-efficacy.[7] Among workers below the median, information raises the effort index by 0.35 standard deviations ($p = 0.002$). Each component moves in the same direction: absenteeism falls by 2.7 percentage points ($p = 0.046$), conditional daily hours rise by 0.048 hours ($p = 0.109$), and the attendance bonus increases by 3.805 USD ($p = 0.031$).

Among workers above the median, the information effect is small and statistically insignificant. It is 0.29 standard deviations smaller than the effect among low-self-efficacy workers ($p = 0.052$), implying an effect of only 0.06 standard deviations ($p = 0.593$). Figure C.1 shows the same pattern across quartiles: the effect is largest in the lowest self-efficacy quartile and declines monotonically. Workers with lower initial self-efficacy thus appear more responsive to information about returns and feasible actions, while those with higher self-efficacy have less scope to adjust these effort margins.

Adding the role model attenuates the effort response even among workers with low baseline self-efficacy. The combined effect is 0.23 standard deviations smaller than the

[7] Table C.3 reports the average effect in the baseline-survey sample. The effects are more noisily estimated but consistent with our full sample results.

Notes: **Table 3 reports heterogeneous treatment effects by baseline self-efficacy index.** *High self-efficacy* is an indicator equal to one if a worker's baseline self-efficacy index is above the sample median. The baseline self-efficacy index is constructed from survey questions measuring workers' confidence in their ability to succeed at work. The index is standardized and higher values indicate greater baseline self-efficacy. The number of observations differs from Table 2 because coverage of the baseline survey was incomplete. Table A.4 describes how the baseline sample differs from the overall study sample. Regressions include production line fixed effects and baseline control variables selected using post-double-selection LASSO. Heteroskedasticity-robust standard errors are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

information-only effect ($p = 0.045$), leaving an effect of 0.12 standard deviations ($p = 0.378$). Similarly, the role-model-only treatment does not increase effort in either self-efficacy group. The narrative therefore offsets information precisely among workers who otherwise respond most strongly.[8]

Psychological responses. In line with this mechanism, we observe an increase in self-efficacy among initially low self-efficacy workers. Column 5 of Table 3 shows a parallel psychological response. Among workers with low baseline self-efficacy, information raises the endline self-efficacy index by 0.256 standard deviations ($p = 0.033$), significantly more than among high-self-efficacy workers ($p = 0.010$). The combined treatment produces a similarly sized gain in self-efficacy, suggesting that the information component raises self-efficacy in both arms. These results support self-efficacy as a plausible channel for the information effect.

However, the information-only and combined treatments raise measured self-efficacy by similar amounts. The role-model narrative may therefore have changed workers' beliefs about the payoff to effort without undoing their confidence in their ability to improve. Specifically, the featured worker's success could have made the returns described in the information videos seem attainable mainly to workers who resembled her. This interpretation is consistent with the similarity results: effort responses to the role-model content are less favorable among workers whose observable characteristics differ more from hers. Workers may therefore believe that they can work harder while doubting that greater effort will yield the reported returns.

6 Effects on Skill Use

The information intervention targeted both effort and task-related improvements with three videos each. The skill videos encouraged workers to learn more difficult tasks and develop broader skill portfolios. These are beneficial to workers. More difficult tasks pay higher piece rates conditional on expected completion time, while broader portfolios reduce downtime by facilitating reassignment when production lines are congested. Appendix B.2 defines the measures.

The information intervention did not increase either the depth or breadth of skill use. Instead, Figure 2a shows declines in the prespecified advanced-skill index (-0.12 standard deviations; $p = 0.023$) and versatility index (-0.11 standard deviations; $p = 0.066$). Sharpened q-values within each outcome family leave these conclusions unchanged (Table D.5). Because the role-model content did not discuss skills, the role-model-only and combined estimates are also negative but smaller and statistically insignificant. Table C.4 reports the full results.

[8] Table D.6 reports the remaining prespecified heterogeneity analyses.

To test whether these declines reflect lower demand for higher-skilled work, the endline survey elicited workers' willingness to pay for off-day training through the subsidy required to attend either an advanced-skill workshop or a workshop teaching basic but new skills. Demand was high: 54 percent of placebo workers would attend without a subsidy, and only 13–15 percent would refuse at the highest subsidy. None of the interventions changed either measure; the estimates are small and statistically insignificant (Figure 2a and Table C.5).

The null effects on training demand suggest that information did not materially change perceived returns to acquiring sewing skills. The declines in administrative skill-use measures may instead be a side effect of the positive effort response. Workers may have focused on immediately adjustable effort margins rather than negotiating for advanced, better-paid tasks; alternatively, greater attendance and longer hours may have required remaining on a narrower set of basic tasks. The saturation analysis provides no systematic evidence that treated workers' advanced tasks were reallocated to placebo coworkers (Table C.7).

6.1 Productivity and Earnings

Information increases effort and working time but reduces skill use, raising the question of whether output and earnings change. Figure 2b and Table C.6 report treatment effects on the logged output, productivity, and earnings measures.

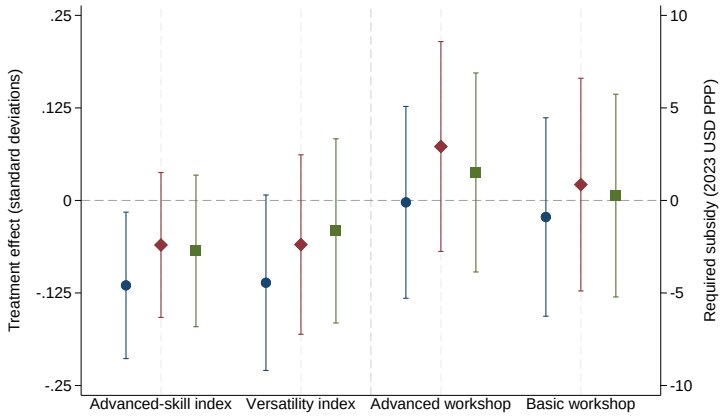

The information-only treatment reduces output per hour by 6.3 percent ($p = 0.073$), consistent with its effect on skill use. Because lower absenteeism and longer hours offset the decline in hourly productivity, output per scheduled day falls by only 3.2 percent and is statistically insignificant ($p = 0.312$). Monthly and hourly earnings change by 0.5 percent and -0.5 percent, with standard errors of 1.5 and 0.5 percent, respectively. Estimates for the role-model-only and combined treatments are also small and statistically insignificant, consistent with their muted effects on effort and skill use.

Thus, greater effort did not raise earnings during the post-treatment period, largely because lower skill use offset the increase in work time. This response need not be suboptimal: additional attendance and hours may be less costly to workers than learning and performing more difficult tasks. However, it is also possible that workers neglect the impact of their effort choice on their skill usage.

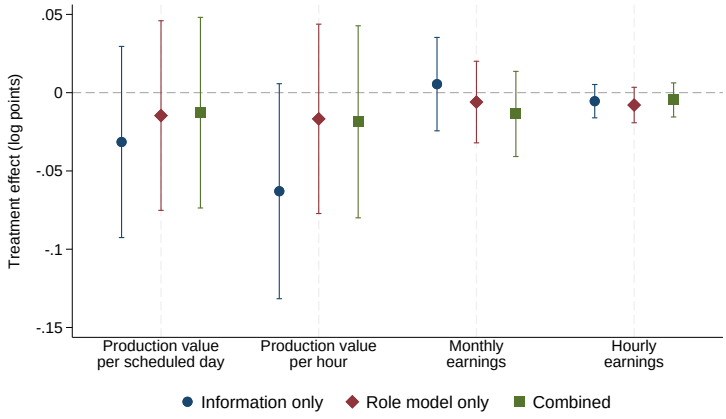

From the firm's perspective, the information group generated similar output at a similar labor cost. Longer hours may nevertheless raise other variable-input costs, such as electricity, while narrower skill use may limit the range of output the firm can produce.

Figure 2: Treatment Effects on Skill-use and Wage Outcomes

(a) Skill Indices and WTP for Skills

(b) Output and Earnings

Notes: **Figure 2 shows estimated treatment effects on skills use, demand for skill training, production value and earnings.** Figure 2a reports effects on skill use and demand for training. The advanced-skill and versatility indices are plotted against the left axis. The advanced-skill index combines whether and how frequently workers performed A- and B-level tasks and the average difficulty of completed tasks. The versatility index combines the average number of tasks performed per day and the total number of distinct tasks performed during the post-treatment period. The two training-demand outcomes, plotted against the right axis, are midpoint-coded estimates of the minimum subsidy workers required to attend either an advanced workshop teaching A-level skills or a basic workshop teaching skills below the A level. The measures are expressed in 2023 USD PPP. A higher required subsidy indicates a lower willingness to participate. Respondents unwilling to attend even with a 70.28 USD (VND 500,000) subsidy are assigned a value of 105.42 USD (VND 750,000). Figure 2b reports effects on four logged outcomes. Production value per scheduled day values output at task-specific piece rates and averages it over all scheduled workdays while the worker remains employed; scheduled workdays without recorded output are assigned a value of zero. Production value per hour divides total production value by total recorded working hours. Monthly earnings include actual piece-rate pay, overtime pay, bonuses and subsidies. Hourly earnings divide total earnings by total recorded working hours. Monetary outcomes are converted to 2023 USD PPP before logarithmic transformation and are winsorized at the 99th percentile. Each point represents the estimated treatment effect from a regression identical to the main specification. Vertical bars indicate 95 percent confidence intervals based on heteroskedasticity-robust standard errors. Tables C.4–C.6 report full regression results.

7 Conclusion

This paper shows that both the content and the packaging of workplace communication matter. In a field experiment with 1,749 garment workers in Vietnam, information about the pay structure and workplace incentives increased short-run effort. A role-model story had no detectable effect alone and eliminated the information-induced gain when paired with it. The combined treatment was more effective among workers who resembled the featured worker, suggesting that narratives must appear relevant and attainable.

Occupational self-efficacy also shapes effort. Among workers with lower baseline self-efficacy, information raised both self-efficacy and effort. Broad beliefs in one's ability to succeed—not only beliefs about specific returns—therefore influence workplace behavior. Personnel practices that strengthen workers' agency may help them act on available incentives.

Our findings also highlight two limitations of information provision as a tool for improving workplace performance. First, although workers increased attendance and working hours, they shifted toward less complex tasks. The intervention therefore left output and earnings unchanged during the follow-up period. Effective communication must balance the behaviors it seeks to influence so that gains along one margin are not offset by reduced performance along another. This highlights potential pitfalls of trying to increase worker productivity or output within complex incentive systems through information. Workers may selectively focus on a subset of behaviors without considering spillovers to other dimensions.

Second, the effort effects weakened by the third month after treatment, potentially because of the reorganization of work. This suggests that sustaining behavioral change in environments with frequent reassignment of tasks, colleagues, and workplaces may require repeated communication that is able to attract attention despite the large volume of social-media content workers consume organically. Short and recurring formats such as episodic social-media dramas may offer a scalable and relatively inexpensive way to reinforce workplace information.

Online Appendices Not for Publication

A Intervention, Sample, Engagement, and Balance

This appendix provides additional information about the intervention and its implementation. It describes the recruitment and survey procedures, video content and delivery, treatment exposure, and the March 2024 change in the production environment.

A.1 Recruitment and Survey Administration

Registration: November 21–27, 2023. In October 2023, the firm provided a roster of 2,386 production workers across six sewing workshops. We randomized the full roster before registration. Research assistants then met workers individually and invited them to join their assigned private Facebook group by scanning a QR code. In total, 1,749 workers (73.3 percent) joined. Reasons for non-enrollment included leaving the firm, transferring to another workshop, being on maternity leave, lacking a smartphone, not using Facebook, and declining to participate. At registration, workers had neither seen group-specific content nor been told that the groups would differ in substantive content. Table A.3 compares enrolled workers with workers who did not register. Table A.2 assesses baseline balance among the 1,749 enrolled workers.

Baseline survey: December 2–9, 2023. We posted the common introductory video and opened the baseline survey on December 2, eight days before the first treatment video. Research assistants reminded workers to respond, and each respondent received 4.2 USD (VND 30,000). By December 9, 1,070 workers had completed the survey, corresponding to 61.2 percent of the enrolled sample. The survey provides the pre-treatment self-efficacy measure used in the heterogeneity analysis. Baseline-survey respondents were younger, more educated, more likely to be female, and more productive than nonrespondents; Table A.4 reports these comparisons.

Weekly surveys. We administered two short surveys during the treatment period, on December 15 and 22. Each took about three minutes to complete. Respondents received 1.4 USD (VND 10,000), and a correct answer to a question about recent video content entered them into a lottery for 14 USD (VND 100,000). To increase coverage, we randomly selected 400 workers in each round for targeted in-person follow-up. The first survey received 835 responses, including 343 from the targeted group; the second received 763 responses, including 331 from the targeted group. Response rates in the targeted groups were therefore 85.8 and 82.8 percent. After excluding responses that could not be matched to an enrolled worker, the exposure analysis in Section A.3 contains 1,579 responses from 1,045 workers.

Endline survey: December 30, 2023–January 14, 2024. We opened the endline survey immediately after the treatment period. It measured post-treatment self-efficacy and demand for skill training. Each respondent received 7 USD (VND 50,000), and research assistants followed up individually with nonrespondents. The survey was completed by 1,554 workers, or 88.9 percent of the enrolled sample. Table A.1 reports completion rates by treatment arm; none differs significantly from the placebo-group rate.

Notes: **Table A.1 reports participation rates by treatment arm at registration, baseline survey, weekly survey and endline survey.** The registration rate uses the number randomized in each arm as its denominator. The baseline-, weekly- and endline-survey completion rates use the number who joined the Facebook group in the corresponding arm as their denominator. Differences and p-values are from tests of equality with the placebo group, conditional on production lines.

A.2 Video Content and Posting Schedule

Section 4 describes the treatment arms and the features held constant across them. Table A.5 instead provides a video-by-video description of the two active interventions. The information series begins with factory-specific wage patterns and the returns to difficult and varied tasks. Later videos present practical steps for acquiring skills, sustaining attention, setting goals, and translating intentions into effort. The role-model series traces the featured worker's experience from initial difficulties and stalled progress to renewed

Table A.2: Balance Tests for Experimental Sample

	Control (1)	Information (2)	Role Model (3)	Combined (4)	p (5)	N (6)
Panel A: Demographics						
Female	0.80	0.81	0.79	0.76	0.22	1749
Tenure (months)	29.97	30.07	30.14	29.89	1.00	1749

Received all the full-attendance bonus	0.46	0.48	0.51	0.50	0.52	1747
Average daily working hours	9.98	9.96	9.98	9.97	0.46	1747

Notes: **Table A.2 reports baseline balance across treatment arms.** Columns 1–4 report group means; column 5 reports p-values from joint tests of equality across treatment arms.

effort, recognition at work and at home, and improved financial circumstances.

Table A.6 records the exact order and release date of every treatment and placebo video. Active and placebo videos were interspersed so that all four groups received posts on the same dates. Videos were released daily during three intervals: December 10–14, December 17–21, and December 24–27. The table also records survey releases, follow-up posts, and announcements of the quiz-lottery winners.

A.3 Treatment Exposure and Content Recall

Figure A.1 plots video-level engagement by treatment arms. Panel A plots the cumulative number of unique viewers per video, and Panel B plots the number of Facebook reactions. Table A.8 shows regressions at the video-group level. Views and emotions are collected more than 30 days after each video was posted.

Facebook provides aggregate engagement statistics but does not verify exposure for each worker. The two weekly surveys therefore collected individual-level measures of self-reported viewing, the number of different videos watched, and recall of recent video content. Table A.7 summarizes 1,579 worker-survey responses from 1,045 unique work-

Table A.3: Baseline Characteristics by Registration Status

	Did not join (1)	Joined (2)	Difference (3)	p-value (4)
Panel A: Demographics

Fraction of attendance bonus received	0.898	0.949	-0.051	0.000
Received all the full-attendance bonus	0.377	0.487	-0.110	0.000
Average daily working hours	9.856	9.969	-0.113	0.000

Notes: **Table A.3 compares randomized workers who did and did not join a study Facebook group.** Characteristics are measured during the August–October 2023 baseline period. The difference is the mean among workers who did not join minus the mean among workers who joined. The reported p-values are from unequal-variance tests of equality of means. Sample sizes vary because some baseline administrative variables are missing.

ers. Because these measures are conditional on survey participation, we use them as engagement checks rather than measures of exposure for every enrolled worker.

A.4 March 2024 Production Transition

The pre-analysis plan specified administrative follow-up from January through March 2024. March marked a factory-wide hiring and training transition. Human-resources records show 334 hires across the two factories in March, including 129 non-office sewing workers. The sewing hires equaled 5.5 percent of the sewing workforce as of February 29 and were more than twice the 61 hired in February. Attendance rosters also contain 139 workers who first appear in March, while 75 workers listed in February do not appear in March. The firm required workers to attend training during this transition, temporarily limiting their usual autonomy.

The main analysis therefore defines January–February as the post-treatment period preceding the factory-wide transition. Appendix C.1 reports treatment effects separately by month, retaining the full follow-up horizon specified in the pre-analysis plan.

Table A.4: Selection Into Baseline Survey

	Non-respondents (N=679) (1)	Respondents (N=1,070) (2)	Difference (3)	p-value (4)

Panel C: Effort measures				
Absenteeism rate	0.043	0.041	0.002	0.554
Average full-attendance bonus	54.924	56.222	-1.298	0.049
Fraction of attendance bonus received	0.942	0.953	-0.011	0.113
Received all the full-attendance bonus	0.476	0.494	-0.018	0.476
Average daily working hours	9.970	9.969	0.000	0.957

Notes: **Table A.4 compares randomized workers who did and did not respond to the baseline survey.** Characteristics are measured during the August–October 2023 baseline period. The difference is the mean among workers who did not respond minus the mean among workers who responded. The reported p-values are from unequal-variance tests of equality of means. Sample sizes vary because some baseline administrative variables are missing.

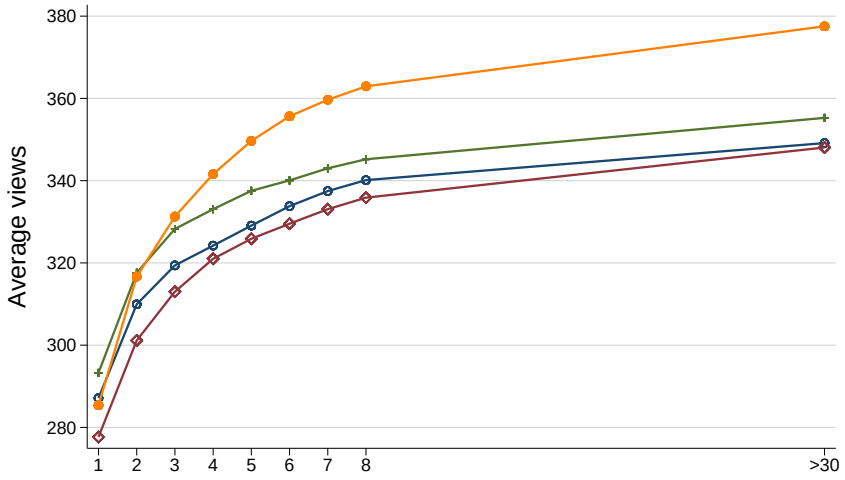

Table A.5: Contents of Video Intervention

Video	Title	Content
Panel A. Information intervention		
INFO 1	How much do people earn at Hualida?	Information about wage distribution.
INFO 2	Did you know? Learning new skills can improve your earnings.	One way of increasing your earnings is to learn difficult tasks because the return to those tasks is higher.
INFO 3	Being an alrounder at work pays off!	Learn multiple tasks so that she can be an all-rounder on her production line.
INFO 4	How to improve your sewing skills?	Information about how to invest in those skills. Workers should show initiative and proactively looking for opportunities to learn.
INFO 5	Working hard pays off!	Effort matters.
INFO 6	Hard to maintain focus at work? Let me give you some tips!	How to increase effort: set a goal, make action plans and evaluate them if not achieved.
INFO 7	Want to earn more? Improve your skills and enhance your work effort.	Summary video. There are two main ways of increasing your earnings: learn different skills and increase your effort.
Panel B. Role model intervention		
RM 1	Success as production worker at Hualida is possible!	Setting the tone: The worker received paycheck and is very happy about the amount. Mention that she struggled at first, just like everyone else.
RM 2	The beginning of my journey at Hualida.	Initial fast learning then reach plateau of productivity. Temporary loss of motivation and no aspiration.
RM 3	How I motivated myself to make progress at Hualida.	Manage to improve productivity and earnings from previous long period of stagnation.
RM 4	Respect by colleagues and managers!	Speaks of recognition by peers and managers for working better.
RM 5	How I became role model for my family.	Recount recognition by partner and child for better work.
RM 6	Success at Hualida has given me financial freedom.	Recount increased financial freedom.
RM 7	You can be successful too!	Summarize overall message of the videos so far. Recount general improvement in happiness and life satisfaction.

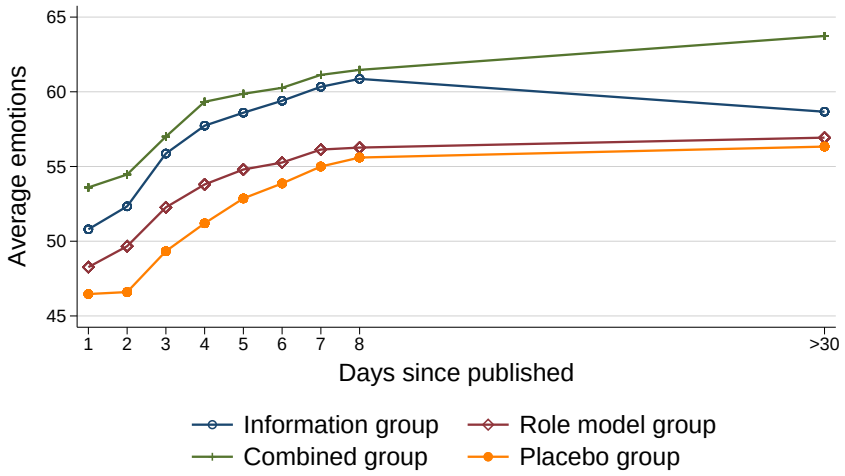

Table A.6: Video Posting and Survey Schedule

Figure A.1: Facebook Video Engagement Over Time

(A) Unique viewers per video

(B) Emotions per video

Notes: **Figure A.1 shows that engagement increased during the first week after publication and followed similar trajectories across the three active-treatment groups.** The figure uses aggregate engagement statistics from four private Facebook groups, one for each experimental arm; each group contained approximately 425 workers. Each point is the unweighted average across the videos posted to the corresponding group, measured at the same number of days after publication. Panel A plots the cumulative number of unique viewers per video. Facebook counts each viewer at most once for a given video, so these values measure unique viewers rather than total viewing events. Panel B plots the number of Facebook reactions, labeled "emotions" by the platform, attached to each video. Unlike cumulative viewer counts, reactions can be withdrawn. A decline in Panel B therefore indicates fewer reactions remaining on the videos, not a decline in cumulative exposure.

Table A.7: Individual-Level Video Exposure and Content Recall

	Watched any video		Number watched		Correct answer	
	Percent	*N*	Mean	*N*	Percent	*N*
All survey responses	97.6	1579	4.11	1540	87.6	1544
Information only	97.8	414	4.04	405	87.3	401
Role model only	98.1	377	3.94	369	85.7	371
Combined	97.7	399	3.93	390	85.3	388
Placebo	96.7	389	4.52	376	92.2	384

Notes: **Table A.7 summarizes two weekly surveys administered during the intervention.** The unit of observation is a worker-survey response; 1,579 responses were provided by 1,045 unique workers. *Watched any video* indicates that the respondent reported watching at least one A Hua video during the preceding seven days. *Number watched* is the reported number of different videos watched during the preceding seven days, calculated among the 1,540 responses reporting a positive count. *Correct answer* indicates a correct response to an incentivized question about content shown in the respondent's Facebook group during the preceding seven days. Joint tests of equality across arms include survey-round and production-line fixed effects and cluster standard errors by worker. The corresponding p-values are 0.62 for watching any video, 0.01 for the number watched, and 0.004 for quiz accuracy. Because video content differed across arms, accuracy differences should not be interpreted as a clean test of differential attention. All statistics are conditional on weekly-survey participation.

Table A.8: Video Engagement Across Treatment Arms

	Without posting-order FE				With posting-order FE			
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)

p-value: Role model = Information (combined)		0.000		0.099		0.008		0.241
Placebo mean	356.04	356.04	49.36	49.36	356.04	356.04	49.36	49.36
Posting-order fixed effects	No	No	No	No	Yes	Yes	Yes	Yes
Observations	56	56	56	56	56	56	56	56

Notes: **Table A.8 show how engagement with videos differs by content**. The unit of observation is a video-group. Views and emotions are collected more than 30 days after each video was posted. Placebo videos are the omitted category. Columns 1–4 exclude posting-order fixed effects; columns 5–8 include them. Heteroskedasticity-robust standard errors are in parentheses.

B Outcome Construction

This appendix defines the outcomes used in the main analysis and the supplementary tables. Unless otherwise noted, the administrative outcomes are aggregated to the worker level over January–February 2024, the first two months after the intervention. Section B.1 describes the effort outcomes, Section B.2 describes administrative measures of task use and survey measures of demand for skill training, Section B.3 describes production value and earnings, and Section B.4 describes the self-efficacy measure.

B.1 Effort Outcomes

The administrative effort outcomes are calculated over scheduled workdays while a worker remains employed. Approved leave and maternity leave are counted as absences. If a worker resigns or is terminated, scheduled days after the exit date are excluded from the denominator rather than coded as absences or zero working hours. The effort estimates should therefore be interpreted as effects on attendance and hours while employed, rather than as effects that incorporate post-exit days.

We define exit using the April 20, 2024 staff roster and monthly payroll records. A worker is classified as having exited by February 29 if the roster records an exit date during January or February or, when the exit date is unavailable, the worker is marked as having left and has no February payroll record. Under this definition, 91 of the 1,749 enrolled workers exited by February 29: 22 of 445 workers in the information-only arm (4.9%), 25 of 414 in the role-model-only arm (6.0%), 23 of 442 in the combined arm (5.2%), and 21 of 448 in the placebo arm (4.7%). The control mean reported in Table D.2 is calculated on the outcome-specific estimation sample and therefore differs slightly from this raw rate.

Construction of the Effort Index We construct the effort index in five steps. First, we standardize each component separately using its mean and standard deviation among enrolled workers with a nonmissing value for that component, pooling all four assignment arms. Second, we reverse the sign of standardized absenteeism, while standardized working hours and the attendance bonus enter positively, so that higher values of every component indicate greater effort. Third, for each set of available components, we estimate the covariance matrix among enrolled workers observed on all components in that set. We invert this matrix and use its normalized row sums as weights, with the weights summing to one. Fourth, we apply these missing-pattern-specific weights to the components available for each worker. Thus, the index can be calculated when at least one component is observed and is missing only when all three components are missing. Finally, we standardize the resulting index using its mean and standard deviation among

workers assigned to the placebo control group. The final index therefore has mean zero and standard deviation one in the control group, and treatment effects are expressed in control-group standard deviations. Of the 1,749 enrolled workers, 1,646 have all three components, 50 have one or two components, and 53 have none, because none of its three administrative components can be linked for them during the outcome period. The index can be calculated for 1,696 workers, and the final regression uses 1,694 observations because two additional workers have missing values for selected baseline controls. This available-component procedure explains why the index regression contains more observations than some regressions for its individual components.

B.2 Skill Outcomes

We use daily production records to measure the tasks that workers performed during January–February 2024. Tasks are classified by the factories from D level to A level, with A-level tasks the most difficult and B-level tasks the next most difficult. *Any A* and *Any B* are indicators equal to one if a worker performed at least one task at the corresponding level during the outcome period. *Frac A* and *Frac B* are the fractions of the worker's observed production workdays on which she performed at least one task at the corresponding level. *Difficulty* averages the worker's daily task-difficulty score, coding D-, C-, B-, and A-level tasks from one to four. Within each worker-day, tasks are weighted by their total standard minutes, i.e., the task's standard time per unit multiplied by units completed. The advanced-skill index combines *Any A*, *Any B*, *Frac A*, *Frac B*, and *Difficulty*. We first standardize each component and then combine the components using inverse-covariance weights. We standardize the resulting index using the placebo-group distribution, so the control group has mean zero and standard deviation one; higher values indicate more advanced task use.

The versatility outcomes capture the breadth of a worker's task portfolio. *Average number of tasks per day* is the mean number of distinct tasks performed on an observed production day, while *Total number of tasks* counts the distinct tasks performed during the outcome period. The versatility index combines the standardized average and total task counts using inverse-covariance weights and is then standardized using the placebo-group distribution. Higher values indicate a broader task portfolio.

We also use the endline survey to measure workers' demand for additional training. Respondents stated the minimum subsidy they would require to attend, on a day off, either an advanced workshop teaching A-level skills or a basic workshop teaching new skills below the A level. We summarize each response in five ways. The subsidy category ranges from one, for attending without a subsidy, to eight, for refusing even a VND 500,000 subsidy; a higher category therefore indicates lower willingness to participate.

The upper-bound measure assigns the upper endpoint of the selected subsidy interval, and the midpoint measure assigns the interval midpoint. For respondents unwilling to attend for VND 500,000, these measures are coded as VND 1,000,000 and VND 750,000, respectively. The remaining outcomes indicate willingness to attend without a subsidy and unwillingness to attend even at the highest offered subsidy. We convert the two monetary measures to 2023 USD using the PPP conversion factor of VND 7,114.3 per USD.

B.3 Wage Outcomes

We distinguish the value of recorded production from workers' actual earnings. Production value is calculated by valuing each completed task at its task-specific piece rate. Production value per scheduled day divides this total by scheduled workdays while the worker remains employed and assigns zero production to scheduled absences. Production value per hour divides total recorded production value by total working hours. These two measures capture the piece-rate value of output and need not equal the amount paid to the worker. Monthly earnings include actual piece-rate pay, overtime pay, bonuses and subsidies, while hourly earnings divide total earnings by total recorded working hours. We average the monthly outcomes over January and February 2024, convert monetary values to 2023 USD, winsorize each outcome at the 99th percentile, and use natural logarithms in the regressions.

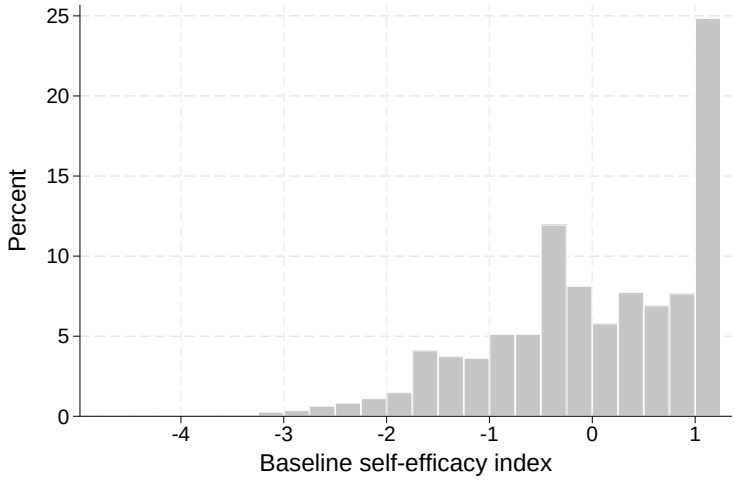

B.4 Self-efficacy

Self-efficacy refers to an individual's belief in their capacity to carry out the actions required to achieve particular performance goals (Bandura, 1977; Locke, 1997). We measure occupational self-efficacy using responses to the following six statements:

- I can remain calm when facing difficulties in my job because I can rely on my abilities.
- When I am confronted with a problem in my job, I can usually find several solutions.
- Whatever comes my way in my job, I can usually handle it.
- My past experiences in my job have prepared me well for my occupational future.
- I meet the goals that I set for myself in my job.
- I feel prepared for most of the demands in my job.

Respondents rated each statement on a five-point Likert scale ranging from "strongly disagree" to "strongly agree." We code the categories from 1 to 5 so that higher values indicate greater self-efficacy, standardize the items, and combine them using inverse-covariance weights.

Figure B.1: Distribution of Baseline Self-efficacy Index

Notes: **Figure B.1 shows the distribution of the baseline self-efficacy index.**

C Supplementary Results

This appendix reports supplementary treatment-effect estimates. Section C.1 traces the information-only effect from the treatment period through the third post-treatment month. Section C.2 reports heterogeneity analyses. Section C.3 reproduces the effort analysis among baseline-survey respondents, the sample used in the self-efficacy analysis. Section C.4 reports effects on administrative task use and demand for skill training, Section C.5 reports effects on production value and earnings, and Section C.6 tests for spillovers within production lines.

C.1 Treatment Effects over Time

Table C.1 estimates information-only treatment effects separately by month. The effort response appears during the intervention and is largest in the first month after it. During December, the information-only treatment increases the effort index by 0.114 standard deviations ($p < 0.10$) and reduces absenteeism by 2.0 percentage points ($p < 0.05$). In January, the effort-index effect rises to 0.207 standard deviations ($p < 0.01$), absenteeism falls by 2.3 percentage points ($p < 0.05$), and working hours increase by 0.028 hours per attended day ($p < 0.10$). In February, the effort index remains 0.151 standard deviations higher ($p < 0.05$), and working hours increase by 0.035 hours ($p < 0.05$). By March, the point estimates for all four effort outcomes are small and statistically insignificant.

Formal comparisons support a fading response for the effort index. The December–March coefficients are jointly unequal ($p = 0.099$), and the January estimate differs from the March estimate ($p = 0.020$). For absenteeism, the corresponding p-values are 0.110 and 0.026. Neither test rejects equality over time for working hours. The January–March

comparison for the attendance bonus is marginally significant, but the pre-treatment coefficients for that outcome are also jointly significant ($p = 0.049$). We therefore interpret the monthly estimates as evidence that the overall effort and attendance response weakened after the first two post-treatment months, rather than inferring persistence or decay from comparisons of month-specific significance levels alone.

Table C.1: Treatment Effects Over Time: Information Group

	(1) Effort index	(2) Absenteeism	(3) Working hours	(4) Attendance bonus

Notes: **Table C.1 reports information-only treatment effects from pooled worker-month regressions containing a full set of indicators for each treatment-arm-by-month cell**. The placebo arm is the omitted group in every month. The rows correspond to December 2023 through March 2024. Every model includes calendar-month and production-line fixed effects. Baseline control variables are selected separately for each outcome using post-double-selection LASSO, with the month and line indicators forced into the selection model. The effort-index components, inverse-covariance weights, and final index are standardized using a common August–October 2023 reference distribution. Standard errors clustered by worker are reported in parentheses. The table reports an omnibus test that the four December–March information effects are equal, a test that the January and March effects are equal, and a joint test that the August–November information coefficients are zero. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

C.2 Heterogeneous Effects

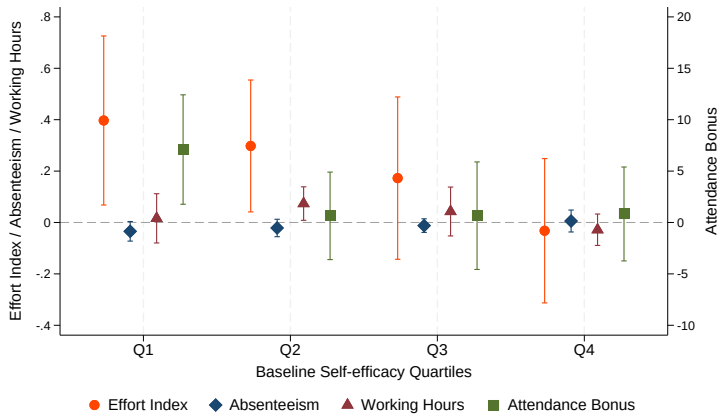

Figure C.1 presents descriptive quartile versions of the prespecified self-efficacy analyses. It plots the information-only effect relative to placebo within each quartile of the baseline moderator. Table C.2 examines whether the role-model-only and combined effects vary with workers' pre-treatment observable similarity to A Hua.

Table C.2: Heterogeneous Role-Model Effects by Similarity Index

	Outcomes

Observations	791	773	788	787

Notes: **Table C.2 reports heterogeneous treatment effects by workers' similarity to the role model featured in the intervention videos.** The sample excludes the information-only treatment arm and includes workers assigned to the placebo, role-model-only, and combined treatment arms. *High similarity* is a binary indicator equal to one if a worker's similarity index is above the median. The similarity index is constructed as the equally weighted average of similarity between the worker and the role model along four dimensions: age, having children, tenure, and gender. Age and tenure are standardized, and similarity on each dimension is defined as one minus the absolute standardized distance from the role model and then normalized. Similarity in gender and having children is coded as an indicator equal to one if the worker shares the same characteristic as the role model. Regressions include production line fixed effects and baseline control variables selected using post-double-selection LASSO. Heteroskedasticity-robust standard errors are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Figure C.1: Heterogeneous Effects by Baseline Self-Efficacy Index Quartiles: Information Group

Notes: **Figure C.1 plots information-treatment effects by baseline self-efficacy quartile.** Coefficients are estimated from regressions of each outcome on treatment indicators interacted with baseline self-efficacy quartile indicators, with the placebo group as the omitted treatment group within each quartile. Regressions include production line fixed effects and baseline control variables selected using post-double-selection LASSO. The plotted points report the estimated effect of the information-only treatment in each quartile. Bars indicate 95 percent confidence intervals.

C.3 Treatment Effects on Survey Respondents

Table C.3 reproduces the main effort specification among workers who completed the baseline survey. This restriction makes the sample comparable to the heterogeneity analysis based on baseline self-efficacy. The pattern matches the full-sample estimates, although the survey-respondent estimates are less precise.

C.4 Effects on Skill Use

Columns 1–6 of Table C.4 report effects on advanced task use. The outcomes capture whether workers performed A- or B-level tasks, the fraction of workdays spent on those tasks, and the average difficulty of completed tasks. Columns 7–10 of Table C.4 reports effects on the breadth of workers' task portfolios, including the average number of tasks performed per day and the total number of distinct tasks performed during the follow-up period. The estimates do not show a systematic increase in advanced or versatile task use. Instead, the information-only arm produces negative estimates for both summary indices, suggesting that its positive attendance response was accompanied by a narrower or less advanced task mix.

Table C.5 report treatment effects on workers' willingness to participate in skill training. The survey elicited the minimum subsidy workers required to attend either an advanced workshop teaching A-level skills or a basic workshop teaching skills below the A level. Across the categorical measures, the upper-endpoint and midpoint measures of the

Table C.3: Treatment Effects on Worker Effort: Baseline Survey Respondents

Observations	1053	1029	1049	1049

Notes: **Table C.3 reproduces Table 2 on the sample of workers who responded to the baseline survey.**

required subsidy, and the indicators for attending without a subsidy or never attending, none of the treatment effects or between-treatment contrasts is statistically significant. The interventions therefore do not appear to have changed workers' demand for either type of training.

C.5 Effects on Output and Earnings

Table C.6 reports effects on production value and earnings. The information-only treatment reduces production value per scheduled day by 0.032 log points, but this estimate is statistically insignificant. It reduces hourly production value by 0.063 log points—approximately 6 percent—with significance at the 10 percent level. The estimated effects on monthly and hourly earnings are 0.005 and -0.005 log points, respectively, and neither is statistically significant. The role-model-only and combined treatments likewise have no detectable effect on production value or earnings. We therefore find no evidence that the increase in attendance generated higher earnings during the follow-up period.

Notes: **Table C.5 reports treatment effects on WTP for skills elicited in the endline survey.** The advanced workshop teaches A-level skills, while the basic workshop teaches skills below the A level. The subsidy-category outcomes range from 1 (willing to attend with no subsidy) to 8 (unwilling to attend even with a VND 500,000 subsidy); hence, higher values indicate a lower willingness to participate. Required subsidy is coded using either the upper endpoint or the midpoint of the interval implied by the respondent's choices. For respondents unwilling to attend even with a VND 500,000 subsidy, the upper-endpoint and midpoint measures are coded as VND 1,000,000 and VND 750,000, respectively. Monetary outcomes are expressed in 2023 USD PPP. "Attend with no subsidy" and "Never attend" are indicator variables. Regressions include production line fixed effects and baseline control variables selected using post-double-selection LASSO. Heteroskedasticity-robust standard errors are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Notes: **Table C.6 reports treatment effects on wage outcomes during the post-treatment period.** All dependent variables are transformed using logarithms. Column 1 measures workers' production output valued at task-specific piece rates and averaged over all scheduled workdays while employed; scheduled workdays without recorded output are assigned a value of zero. Column 2 reports hourly piece-wage value, calculated as total production value divided by total recorded working hours. These production-value measures are accounting measures and do not equal workers' actual pay. Column 3 reports average monthly earnings. Column 4 reports hourly earnings, calculated as total earnings divided by total recorded working hours. Monetary outcomes are converted to 2023 USD PPP before logarithmic transformation and are winsorized at the 99th percentile. Regressions include production line fixed effects and baseline control variables selected using post-double-selection LASSO. Heteroskedasticity-robust standard errors are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

C.6 Spillover Effects

Workers on the same production line may affect one another through information sharing, peer behavior, or changes in task assignment. Spillovers are especially plausible in sewing lines because production tasks are linked and managers move workers across tasks to balance the line. The randomized saturation stage allows us to test for such effects. The 59 production lines were assigned to high or low treatment intensity: 90 percent of workers received an active treatment on high-intensity lines, compared with 50 percent on low-intensity lines. We estimate spillovers by comparing placebo-assigned workers across the two types of lines.

$$y_{il} = \alpha + \sum_{g \in \{I,R,C\}} \beta_g T_{gil} + \delta H_l + \sum_{g \in \{I,R,C\}} \kappa_g (T_{gil} \times H_l) + W_l' \Pi + X_i' \Gamma + \varepsilon_{il}, \tag{3}$$

Here, T_{gil} indicates worker i's assignment to active arm g, and H_l indicates that production line l was assigned to high treatment intensity. The omitted group is placebo-assigned workers on low-intensity lines. Accordingly, δ is the spillover contrast, β_g is the direct assignment effect of arm g on low-intensity lines, and κ_g measures how that direct effect differs on high-intensity lines. W_l contains fixed effects for the workshop strata used in the saturation assignment, and X_i contains baseline worker covariates selected using post-double-selection LASSO. Because H_l varies only across production lines, the regression does not include production-line fixed effects. Standard errors are clustered by production line.

Table C.7 reports the results. The high-intensity contrast among placebo-assigned workers is close to zero for the effort index, advanced-skill index, and versatility index: the estimates are 0.001, 0.007, and -0.034 standard deviations. None is statistically significant. Among the individual outcomes, only the probability of performing any B-level task differs significantly by line intensity, and the remaining components do not show a common pattern.

The direct information effect on the effort index is also similar across saturation levels. Its estimated effect is 0.136 standard deviations on low-intensity lines, and the information-by-high-intensity interaction is 0.071 standard deviations and statistically insignificant. The combined-treatment effect remains near zero at both intensity levels. The saturation results therefore provide no systematic evidence that within-line spillovers explain either the main effort response, the decline in summary skill use, or the attenuation produced by adding the role-model narrative.

Notes: **Table C.7 tests for within-line spillover effects using randomized variation in treatment intensity across production lines.** High intensity indicates that a larger share of sampled workers on the production line was assigned to an active treatment. The Information, Role model, and Combined coefficients report direct assignment effects on low-intensity lines; their interactions with High intensity test whether those effects differ on high-intensity lines. The High intensity coefficient compares placebo-assigned workers on high- and low-intensity lines and is the spillover estimand. Regressions include workshop-stratum fixed effects and baseline controls selected using post-double-selection LASSO; they do not include production-line fixed effects. Standard errors, reported in parentheses, are clustered by production line. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

D Full Prespecified Main Outcomes, Robustness and Heterogeneity

This appendix presents the main outcomes and prespecified heterogeneity analyses in the pre-analysis plan (PAP) with the paper's current empirical specification. The administrative main-outcome estimates use the first three post-intervention months (January–March 2024), while robustness checks and prespecified heterogeneity estimates use the first two months (January–February 2024). Willingness to pay was elicited in the immediate post-intervention survey and therefore has no monthly outcome window. Throughout, we use the paper's current production-line fixed-effects specification, outcome-specific post-double-selection LASSO controls, and heteroskedasticity-robust standard errors.

D.1 Main Outcomes

Table D.1 reports the full set of prespecified advanced-task and task-versatility outcomes. Over January–March 2024, the information-only intervention reduces the advanced-skill index by 0.109 control-group standard deviations ($p = 0.024$) and the versatility index by 0.086 standard deviations ($p = 0.092$). The factorial interaction is positive for both indices, although only the advanced-skill interaction is marginally significant ($p = 0.060$). The component outcomes show that the combined arm performed A-level tasks less often, but the broader pattern does not indicate a systematic treatment-induced increase in skill use.

Table D.1: Treatment Effects on Skill Use

	Advanced index	Any A	Frac A	Any B	Frac B	Difficulty	Versatile index	Tasks per day	Total tasks

Notes: **Table D.1 reproduces Table C.4 using a three-month post-treatment window.**

Table D.2 reports the prespecified effort index, its components, 90-day exit, and production value per scheduled workday. Over January–March 2024, the information-only intervention increases the effort index by 0.111 control-group standard deviations ($p =$

0.080), although its effects on the individual components are imprecisely estimated. The combined-arm effect is 0.182 standard deviations smaller than the information-only effect ($p = 0.004$). None of the interventions measurably changes exit within 90 days. The estimated information-only effect on log production value per scheduled workday is -0.043 (SE $= 0.030$; $p = 0.148$) and is not statistically distinguishable from zero.

Table D.2: Treatment Effects on Effort, Retention, and Production Value

Notes: **Table D.2 reports the prespecified effort index, its components, exit, and average daily production value using a three-month post-treatment window.**

D.2 Alternative Covariate Adjustment

Table D.3 compares the main PDS-LASSO specification with a model containing only production-line fixed effects. Both panels define treatment by actual Facebook-group entry and use the same outcome-specific samples. The similar estimates indicate that covariate selection does not drive the results.

D.3 Re-randomization Inference

Table D.4 reports complementary intention-to-treat estimates based on original randomized assignment. It presents conventional robust p-values and p-values generated by the PAP assignment algorithm. Because the main analysis defines treatment by actual Facebook-group entry, these ITT estimates need not reproduce the main as-treated coefficients. The information effects on effort and advanced task use remain significant under rerandomization inference; the versatility effect does not ($p = 0.113$).

D.4 Multiple-testing Adjustments

Table D.5 reports two-stage sharpened q-values, calculated within each outcome family and separately for each treatment estimand. Treatment is defined by actual Facebook-

Notes: **Table D.4 reports robustness to a two-stage rerandomization inference.** This table shows intention-to-treat estimates using original randomized assignment; the main tables instead use actual Facebook-group entry. Regressions include production-line fixed effects and outcome-specific controls selected by post-double-selection LASSO. Robust p-values use heteroskedasticity-robust standard errors. Rerandomization p-values are two-sided, line-cluster-studentized p-values based on 9,999 accepted assignments generated using the PAP two-stage assignment procedure and balance criterion. Administrative outcomes cover January–February 2024.

group entry, matching the main analysis. For the information treatment, the effort index and both skill-use indices remain significant at a 10 percent false-discovery-rate threshold; the willingness-to-pay and production-value outcomes do not.

Table D.5: Multiple-Testing Adjustments for Main Outcomes

Family	Outcome	Information	Role model	Combined	Interaction

Effort	Effort index	0.002 [0.002]	0.690 [1.000]	0.903 [1.000]	0.080 [0.087]
Production value	Log daily production value	0.312 [0.454]	0.636 [1.000]	0.681 [1.000]	0.431 [0.757]

Notes: **Table D.5 shows robustness to multi-testing adjustments.** Each cell reports the unadjusted p-value followed in brackets by the two-stage sharpened q-value of Benjamini, Krieger, and Yekutieli (2006), implemented as in Anderson (2008). The false-discovery-rate adjustment is performed separately for each treatment estimand within four prespecified families: willingness to pay (advanced- and basic-workshop WTP), skill use (advanced-skill and skill-versatility indices), effort (effort index only), and production value (log daily production value). Raw p-values come from the paper's current specification, which includes production-line fixed effects, outcome-specific baseline controls selected by post-double-selection LASSO, and heteroskedasticity-robust standard errors. The interaction is the factorial Information $\times$ Role model contrast. WTP is measured immediately after treatment; administrative outcomes cover January–February 2024.

D.5 Prespecified Heterogeneity

Table D.6 shows eight prespecified median-split analyses. The clearest pattern repeats the paper's existing result: the information-only effect on effort is larger among workers with lower baseline self-efficacy and lower baseline effort. The high-minus-low interaction is -0.304 standard deviations for self-efficacy ($p = 0.043$) and -0.264 standard deviations for baseline effort ($p = 0.024$). Several additional interactions are individually significant or marginally significant, including larger advanced-skill and production-value effects among workers with higher baseline social-media use.

Notes: **Table D.6 shows prespecified heterogeneity analyses.** Each cell reports the treatment effect for workers at or below the sample median (L), the treatment effect for workers above the sample median (H), robust standard errors in parentheses, and the robust p-value for equality of the two effects. Administrative outcomes use January–February 2024; willingness-to-pay outcomes come from the immediate post-intervention survey. Advanced WTP and Basic WTP are the ordered WTP-category measures for the corresponding workshops and are coded so that higher values indicate greater willingness to pay. Specifications include production-line fixed effects and outcome-specific baseline controls selected by post-double-selection LASSO. Social-media use is baseline hours per day. The index outcomes are normalized to the control-group mean and standard deviation in their corresponding samples. Stars denote $p < 0.10$, $p < 0.05$, and $p < 0.01$.
